A huge increase of thermal conductivity κ is observed at the phase transition in stoichiometric NaV_2O_5 . This anomaly decreases and gradually disappears with deviation from stoichiometry in $\text{Na}_{1-x}\text{V}_2\text{O}_5$ ($x = 0.01, 0.02, 0.03$, and 0.04). This behavior is compared with that of pure and Zn-doped CuGeO_3 where only modest kinks in the $\kappa(T)$ curves are observed at the spin-Peierls transition. The change of κ at critical temperature T_c could be partially attributed to the opening of an energy gap Δ in the magnetic excitation spectrum excluding the scattering of thermal phonons on spin fluctuations. However, the reason for such a strong anomaly in the $\kappa(T)$ may lie not only in the different energy scales of CuGeO_3 and NaV_2O_5 , but also in the different character of the phase transition in NaV_2O_5 which can have largely a structural origin, *e.g.* connected with the charge ordering.

June 12, 1998

Since the discovery of a spin-Peierls (SP) transition in CuGeO_3 [1] and NaV_2O_5 [2] numerous experimental and theoretical studies were continued to reveal the main features of this phenomenon in inorganic compounds. While considering that the study of CuGeO_3 remains very active, the main physical properties of this compound are quite well known by now. CuGeO_3 belongs to the orthorhombic space group Pbmm . The structure contains magnetic chains of Cu^{2+} ($3d^9$, $S = 1/2$) ions parallel to the c axis. The SP transition observed at $T_c \simeq 14$ K is marked by an exponential drop of the magnetic susceptibility and a simultaneous lattice dimerization along the a and c axes. Due to the magnetoelastic coupling the exchange constant between neighboring spins on the chain also alternates and the singlet ground state in the dimerized phase is separated from the band of excited triplet states by an energy gap Δ of about 25 K [3, 4].

In comparison with CuGeO_3 , only few and somewhat contradictory data are presently available on the specific features of the phase transition in the mixed ($\text{V}^{4+}/\text{V}^{5+}$) or intermediate ($\text{V}^{4.5+}$) valence compound NaV_2O_5 . A rapid decrease of the magnetic susceptibility below $T_c \simeq 35$ K suggests the formation of a nonmagnetic spin-singlet ground state. The simultaneous formation at this temperature of a superlattice structure characteristic of a SP transition was confirmed by X-ray measurements [5], while the opening of an energy gap ($\Delta \simeq 100$ K) in the magnetic excitation spectrum was observed in inelastic neutron experiments [6]. These data, as well as the results of NMR [7] and ESR [8] studies, are strong evidence of the presence of $S = 1/2$ chains considered as a necessary condition for a SP transition. On the other hand, the two-step phase transition found in specific heat and thermal expansion measurements [9] make a simple SP scenario for this transition in NaV_2O_5 not so evident.

The main controversy concerning the nature of the phase transition in NaV_2O_5 arises from the uncertainty of its crystal structure identification at room temperature. The X-ray diffraction pattern of single crystals fits well enough with both space groups $\text{P2}_1\text{mn}$ and Pmmn [10-13]. In both cases the layers of edge/corner-sharing tetragonal VO_5 pyramids connected in the $a - b$ plane are stacked along the c axis of the structure while the Na^{1+} ions are situated

between these layers. In the former non-centrosymmetric structure, there exists alternating chains of nonmagnetic V^{5+} ions and magnetic V^{4+} ones ($3d^1$, $S = 1/2$) aligned along the b axis (see *e.g.* Fig. 1 of Ref. [2]). In the latter structure, all the V sites are crystallographically equivalent, which results formally in a random distribution of the V^{4+} and V^{5+} ions, or in a localization of electrons on V-O-V molecular orbitals on the rungs of the ladders running along the b axis (see *e.g.* Fig. 1 of Ref. [13]). In such a situation a one-dimensional magnetic behavior does not come about straightforwardly but can still be justified [13-15].

In order to clarify a picture of the phase transition in NaV_2O_5 , more experimental data are necessary. One of the few experimental techniques not yet applied to the study of SP transitions in metal oxides is the measurement of thermal conductivity which can provide useful information on the interaction of elementary excitations in these compounds.

In this letter we report on the first, to the best of our knowledge, such measurements, which show a surprisingly strong effect in NaV_2O_5 , in comparison with the rather weak anomaly observed in $CuGeO_3$. A possible interpretation of this effect is considered below and it is concluded that the nature of the phase transition in NaV_2O_5 may be more complicated than previously assumed.

Single crystals of $CuGeO_3$ and $Cu_{0.98}Zn_{0.02}GeO_3$ were grown in Paris University by a floating zone method [16]. Single crystals of stoichiometric NaV_2O_5 were grown in Tokyo University by the self-flux method [17]. Single crystals of non-stoichiometric $Na_{1-x}V_2O_5$ ($x = 0.01, 0.02, 0.03$, and 0.04) were prepared by heating a small crystal of stoichiometric NaV_2O_5 embedded in a large quantity of $Na_{1-x}V_2O_5$ powder in an evacuated silica tube at $650^\circ C$ for one week. The non-stoichiometric samples of $Na_{1-x}V_2O_5$ contain vacancies on the Na sites. Typical dimensions of the crystals used in the thermal conductivity measurements were $0.2 \times 0.8 \times 4.0$ mm³. The largest dimension coincided with the dimerization axis, *i.e.* the c axis in the case of $CuGeO_3$, and the b axis in the case of NaV_2O_5 . The smallest dimension coincided with the a axis in the layered structure of $CuGeO_3$ and c axis in the layered structure of NaV_2O_5 . In most cases, measurements were performed in the direction of dimerization, but in $CuGeO_3$ thermal conductivity was measured also along the b axis. The measurements were performed by the longitudinal steady-state four probe method [18] with a temperature gradient equal to 2% of the current temperature. The sample holder, surrounded by a special shell to suppress the thermal radiation, was placed into the vacuum chamber evacuated to better than 10^{-6} bar. The sample temperature and the temperature gradient were stabilized to better than 0.01% by an Oxford intelligent temperature controller with calibrated "Allen-Bradley" carbon resistors. Due to the relatively small dimensions of the samples the error in the determination of the absolute values of thermal conductivity was not better than 10%, while the precision on the thermal conductivity variations was about 1.5 %.

The experimental results obtained in the c and b directions for pure $CuGeO_3$ and for the Zn-doped sample are shown in Fig. 1. A broad phonon maximum of κ is observed at $T = 23.3$ K in the c direction, while it is not well pronounced in the b direction. The absolute value of κ in the b direction is approximately three times lower than that in the c direction. The kinks on the $\kappa(T)$ curves are evident at the temperature of the SP transition. The SP transition temperature in the Zn-doped sample is reduced to $T_c = 10.6$ K to be compared to that of the pure sample $T_c = 14.2$ K. The absolute value of κ at the SP transition in the doped sample is significantly smaller than that in the pure sample.

The thermal conductivity of stoichiometric NaV_2O_5 exhibits a much more dramatic variation in the temperature range studied. As shown in Fig. 2, the thermal conductivity exhibits a broad maximum at $T \simeq 70$ K and decreases upon approaching the SP transition. At T_c a sharp upturn of κ occurs so that a five times increase of thermal conductivity accompanied by a subsequent decrease of κ upon cooling to liquid helium temperature takes place. A behavior similar to the one described above can be seen in non-stoichiometric samples of $Na_{1-x}V_2O_5$ ($x = 0.01, 0.02, 0.03$, and 0.04) with the progressively less pronounced maximum below T_c , as shown in Fig. 3. The position of the low temperature maximum remains unchanged in non-stoichiometric samples but absolute values of κ gradually decrease with x . Certain variation in the high temperature slopes and the vertical shift between the curves obtained for 0 and 1% and the curves for 2, 3 and 4% Na deficiency can be tentatively ascribed to a variation in the crystals morphology. These crystals can be easily cleaved perpendicular to the c axis, resulting in an uncontrolled extra scattering of the phonons on planar defects. The spin-Peierls transition temperatures in $Na_{1-x}V_2O_5$ determined from the positions of the minimum on the $\kappa(T)$ curves are shown in Fig. 4, where the solid curve is drawn as a guide for an eye. The suppression of T_c by the Na-deficiency was observed earlier in X-ray critical scattering measurements [19].

Since no quantitative treatment of the transport phenomena for the spin-Peierls systems exists, we applied the Boltzmann equation for the analysis of the experimental data. In this approach the phonon thermal conductivity $\kappa \sim vlC$ is determined by the sound velocity v , the mean free path of phonons l , and the specific heat C which depends on the number of elementary excitations. The interactions of the phonon and the spin subsystems can be taken into account through the variation of the phonons mean free path. In the absence of these interactions, the mean free path of the phonons increases upon cooling and eventually saturates while their number decreases. These opposite tendencies result in a phonon maximum T_m on the $\kappa(T)$ curves. The estimated phonon mean free path in $CuGeO_3$ is still much less than the sample dimensions; we believe that this is caused by the phonon scattering on planar defects

in the layered structure of this compound. The difference in the absolute values of the thermal conductivity in the b and the c directions in CuGeO_3 can naturally be attributed to a factor three difference in ultrasonic velocities, *i.e.* $2.7 \cdot 10^3 \text{ m/sec}$ in the b direction and $8.0 \cdot 10^3 \text{ m/sec}$ in the c direction [20]. On the other hand, the small thermal conductivity value of in the $\text{Cu}_{0.98}\text{Zn}_{0.02}\text{GeO}_3$ sample as compared with that of the pure CuGeO_3 sample reflects the increased number of scattering centers in the doped sample.

Anomalies observed in the temperature dependence of the thermal conductivity at the spin-Peierls transition can be naturally connected with the change of the crystal lattice and with the formation of the energy gap in the magnetic excitation spectrum. The mutual positions of the temperatures of the phonon maximum T_m and of the spin-Peierls transition T_c is of crucial importance for the analysis of these anomalies. The phonon maximum in CuGeO_3 is reached at $T_m > T_c$. In this case a possible decrease of the phonon scattering on spin fluctuation at T_c cannot significantly influence the thermal conductivity, because the phonon mean free path is already large, and only modest kinks on the $\kappa(T)$ are observed. From the behavior of NaV_2O_5 we have to conclude that the situation here is exactly opposite. If the maximum of κ at 70 K would have the same origin, we would not be able to explain such a strong increase of κ below T_c . Therefore we have to assume that the decrease of κ below 70 K in NaV_2O_5 is of a different nature, and most probably can be explained by the enhancement of phonon scattering on approaching the phase transition. The ordering occurring below T_c apparently switches off this extra scattering and leads to a huge increase of the thermal conductivity. No variation of the sound velocity at T_c can explain the observed behavior of the thermal conductivity in NaV_2O_5 . While no data for the absolute value of the sound velocity are available, a longitudinal velocity variation $\Delta v/v \sim 10^{-3}$ was observed at T_c preceded by a precursor effects observable below 70 K [21].

Several factors may play a role in the much stronger enhancement of the thermal conductivity below T_c in NaV_2O_5 as compared to CuGeO_3 . The spin gap is much larger in NaV_2O_5 ($\sim 100 \text{ K}$ vs $\sim 25 \text{ K}$ in CuGeO_3). Opening of this gap switches off spin-phonon scattering for phonons with frequencies less than Δ . A four times larger spin gap in NaV_2O_5 implies that much more phonons will now strongly contribute to thermal conductivity below T_c . This picture could, in principle, have allowed also to explain the behavior of the thermal conductivity of NaV_2O_5 as a function of the deviation from stoichiometry. Magnetic measurements show that, in contrast with the relatively small suppression of T_c with x , the drop of magnetic susceptibility below T_c is strongly reduced and for $x = 0.03 - 0.04$ it nearly vanishes. This shows that the spin gap is now, to a large extent, filled by magnetic excitations. Correspondingly, the phonon-spin fluctuation scattering is being restored, which suppresses the increase of κ below T_c in non-stoichiometric samples.

However, the comparison with CuGeO_3 shows that pure spin-phonon scattering is hardly sufficient to explain huge increase of κ observed. Magnetoelastic coupling in NaV_2O_5 is not strong enough, which follows *e.g.* from the very weak dependence of T_c on magnetic field [23]. We believe that the huge increase of the thermal conductivity in NaV_2O_5 can be related to the specific features of the phase transition in this compound. If the crystal structure above T_c is indeed that obtained in recent studies [11-13], all V ions are on the average equivalent, *i.e.* the $\text{V}^{4.5+}$ ions. Such a state can be visualized as the (dynamic) random mixture of V^{4+} and V^{5+} . If slow enough, these charge fluctuations can strongly enhance phonon scattering and reduce thermal conductivity similar to a situation in glasses. The phase transition may then be accompanied, or even caused, by the charge ordering [22] at which this extra scattering mechanism is switched off. The opening of a spin gap may then be not so much a driving force but a consequence of this ordering. The transition from the disordered glass-like phase to an ordered one could explain the strong enhancement of the thermal conductivity below T_c . This picture can also explain the observation [23] that the total entropy of the transition in NaV_2O_5 is larger than the pure spin one.

Although our measurements do not allow to draw a final conclusion about the microscopic picture of the changes occurring at the phase transition in NaV_2O_5 , the qualitative difference observed in the behavior of CuGeO_3 and NaV_2O_5 can be taken as an evidence that the nature of the transition in NaV_2O_5 is more complicated than in CuGeO_3 and most probably directly involves lattice and charge degrees of freedom, *e.g.* in a form of charge ordering. Further experiments, especially neutron scattering, should shed light on the microscopic picture of the spin-Peierls transition in NaV_2O_5 and should clarify the nature of the strong anomaly in the thermal conductivity of NaV_2O_5 reported in this letter.
